INTRODUCTION

During 2007 alone, attackers created over 700,000 new malicious programs [1, 2]. While this number appears daunting, modern anti-virus (AV) systems have dealt with this crop successfully every year, by using sophisticated signature and behaviour detection techniques. All of the new viruses are, as far as we know, the product of human engineering. Here we discuss the possibility of an alternative form of design: the emergence of novel function in an autonomously evolving piece of malware.

The possibility of autonomously evolving computer programs is not new. Artificial Life (‘Alife’) researchers have studied self-replicators in computer environments since 1979 [3], and the first autonomously mutating self-replicating computer programs were introduced by Ray in 1992 [4]. More recent systems such as the Avida platform have established that Darwinian evolution of computer programs can be used to study evolutionary biology and genetics [5, 6]. As opposed to computer malware, Alife systems are squarely aimed at the research environment. In these systems, the code is implemented with small, well-defined instruction sets that are highly evolvable; that is, the probability of a mutation leads to another functional program is high (of the order of several to tens of per cents). Most standard computer languages are not robust in this manner. For example, the x86 instruction set only tolerates very few mutations (of the order of fractions of a per cent of the code [7]). Alife systems also differ in that they implement simulated environments where specific program behaviours are rewarded. While this setting is very different from the standard computer malware paradigm, computer virus researchers already hinted at the idea of autonomously evolving malware in the early 1990s [8]. In particular, Spafford performed an exhaustive review of computer viruses under the Artificial Life perspective confirming the absence of functional evolution in such programs [9]. Although the possibility of an autonomously evolving virus – as the one discussed here – was mentioned, it was quickly dismissed as a task too daunting and requiring a very large implementation, possibly larger than the OS itself. More recently, the idea has resurfaced, with a higher emphasis this time on the outcome [10] and the possible mechanics of its emergence [11]. We argue here that apart from a hint and some failed implementation attempts (e.g., W32/Zellome, see [12]), self-evolving malware has yet to appear. The concept itself, however, is relatively simple, and the consequences of the release of evolving malware should be studied.

ABSTRACT

Recent advances in anti-malware technologies have steered the security industry away from maintaining vast signature databases and into newer defence technologies such as behaviour blocking, application whitelisting and others. Most would agree that the reasoning behind this is to keep up with the arms race established between malware writers and the security community almost three decades ago. Still, malware writers have not as yet created new paradigms. Indeed, malicious code development is still largely limited to code pattern changes utilizing polymorphic and metamorphic engines, as well as executable packer and wrapper technologies. Each new malware instance retains the exact same core functionality as its ancestor and only alters the way it looks. What if, instead, malware were able to change its function or behaviour autonomously? What if, in the absence of human intervention, computer viruses resembled biological viruses in their ability to adapt to new defence technologies as soon as they came into effect?

In this paper, we will provide the theoretical proof behind malware implementation that closely models Darwinian evolution.

Biological viruses are under constant attack by immune systems and artificial drugs. Yet they systematically manage to evolve new functionalities that circumvent such countermeasures, leading to recurrent epidemics. According to the biological analogy, evolvable malware will be able to alter its functionality by autonomously incorporating behaviours freely available to it by the numerous discoverable APIs. The new behaviour profiles would constantly be screened by security software in the same way natural selection acts on biological organisms. In the end, the malware instances that are better equipped to survive countermeasures will be able to proliferate more efficiently. Such malware poses a real threat to the current methods of detection due to the vast numbers of functions it can adopt and that cannot possibly be screened for. Furthermore, it is likely that clean-program functionality will be favoured amongst such behaviours since it shields malware that is mimicking clean programs from behaviour blocking. As a consequence, we predict that behaviour-based virus detection would quickly become ineffective if malware can evolve based on the Darwinian paradigm.

DARWINIAN EVOLUTION VERSUS MALWARE EVOLUTION

Evolution as a process requires the presence of three simple elements: replication, variation and differential fitness. Replication allows for inheritance, and in particular the inheritance of variations, introduced by different mechanisms of mutation. These variations are then selected for or against via the competition of individuals over limited resources. The competition leads to differential fitness, i.e. differences in
reproductive success between individuals within a population. Mutations that provide organisms with a reproductive advantage over others (beneficial mutations) will tend to propagate to future generations. It is important to note that the fraction of beneficial mutations (among all those that can occur) is usually very small, with most mutations being deleterious and the rest neutral. Nonetheless, given the long timescale available to biological evolution along with large population sizes, such gradual stepwise beneficial changes will lead to the emergence of complexity [13].

Some have argued that neither the geological timescales nor the large populations that are germane to biological evolution will be available to evolving computer malware. However, generation times for computer viruses are many orders of magnitude shorter than even bacterial generation times, and furthermore selective pressures are expected to be much stronger and mutation rates higher, speeding up evolution [14]. We should note here that geological times, in contrast to popular belief, are not a prerequisite for the appearance of evolutionary change, even in biological evolution. The emergence of new functional complexity on much smaller timescales than geological ones has recently been observed in very different experiments. A 36-year experiment with lizards, for example, has shown that such a comparatively short time frame is sufficient for major adaptive morphological changes to arise, such as novel morphological structures in the form of caecal valves [15]. Also, in a long-term experiment with *E. coli* bacteria, one particular strain evolved the ability to metabolize a new carbon source (citrate) after about 31,500 generations, a complex adaptation that required a multitude of mutations [16]. Given the drastically shorter generation time of computer viruses, generations of this order of magnitude can be achieved within weeks at most.

During the three decades of their existence, computer viruses have moved from simple replicators to advanced polymorphic and metamorphic implementations [17]. The underlying goal of this progression has been to increase the variability of the virus’s signature to the point that tracking different instances of the same virus becomes too daunting a task. Nonetheless, even for the most sophisticated metamorphic viruses [18], the specific functionality and overall behaviour of the virus remain intact. Signature obfuscation, or as we will refer to it here ‘cryptic variation’, will not allow for the discovery of new functionality. What true Darwinian evolution can accomplish is vastly different, because it is the process responsible for the *de novo* generation of all of the complexity of life. The variation observed in surviving lineages of biological viruses (as compared to their ancestors) is a direct result of information ‘exchange’ between the virus and its environment. Simply put, biological viruses are constantly testing new ways of exploiting environmental resources via the process of mutation. In contrast, computer viruses do not exhibit such traits, relying instead on changing their appearance to avoid detection. Functional (as opposed to cryptic) variation, such as the discovery of a new exploit or the mimicry of non-malicious behaviour masking malicious actions, is not part of the arsenal of current malware. While there are examples of functional variation that have occurred by chance (reviewed below in support of our hypothesis) there are no examples of computer malware that exhibits intentional functional change between generations. In the absence of functional variation, differential fitness will never be realized in computer viruses since the reproductive success of offspring remains unchanged. In the event that a behavioural signature is developed for the virus, the entire population, including the cryptic variants, is affected equally. In this case, the functional/behavioural uniformity of the virus population would force all of it to extinction by the countermeasure. Functional variants, on the other hand, because of the variation in behaviour, can escape behaviour-based detection methods. Below, we investigate the theoretical possibility of functional variation in computer viruses and their consequences.

**MODEL IMPLEMENTATION**

Suppose, malware $M$ is comprised of an arbitrary number of malicious functions:

$$M = \{M_1, M_2, M_3, \ldots, M_N\}.$$  

An evolutionary function $EF \in M$, is introduced into the existing set:

$$M = \{M_1, M_2, M_3, \ldots, M_N, EF\}.$$  

EF has the ability to generate new functional code $N$ after each generation of $M$, with a given probability. This can be achieved by different methods, including via the insertion of code extracted from randomly selected APIs present in the malware’s native environment (for example, extraction of function calls that are part of the *Windows API*). Alternatively, in the case of a script threat, extraction of script code from other scripts might also serve the same purpose. In any case, the resulting malware $M$ now consists of the set

$$M(EF) = \{M_1, M_2, M_3, \ldots, M_N, EF, N_1, N_2\},$$

where $N = N(EF)$.

The newly generated function $N$ need not necessarily be malicious. Also, the $M_i$ might trigger anti-virus responses individually or as a combination of each other. The malware $M(EF)$ is now an evolvable threat.

Researchers that envisioned how autonomously evolving malware could be coded have largely focused on binary code manipulation [8,11]. The high percentage of lethal mutations that would be experienced by such malware (due to the brittleness of the code) would forbid evolution from occurring. Consequently, the need for an ‘evolvable’ language or meta-language of implementation becomes apparent. While some work in this direction has been undertaken [7], the prospects for such a design are daunting. By relying instead on functional code that is already present in the malware’s environment, the problem is reduced to finding a way of adopting that functionality in the malware code, instead of creating a language that can code for that functionality autonomously.

Another major consideration with such an implementation is the actual coding of EF itself, as it might appear to represent a static component for which a signature could be produced. However, the EF could use any number of advanced polymorphic or metamorphic engines to hide itself from detection. The ongoing
effort by the anti-virus community to avoid maintaining the
generate large signature databases of the past, combined with the
the advanced metamorphic engines used by viruses such as
W95/Zmist [19] make a cryptic EF implementation feasible. In
fact, it is highly probable that EF’s presence can be fully
disguised by M. By simulating non-malicious behaviour for
example, malware would at best be classified as a false positive
even if EF is detectable. Given the anti-virus industry’s aversion
to false positives, it is conceivable that malware would exploit
this loophole and autonomously and forcefully mimic clean
application behaviour.

FUNCTIONAL EVOLUTION IN CURRENT
SECURITY ENVIRONMENTS

Adapting to security environments can be illustrated via a
number of examples. In this section, we list several ways in
which random changes can lead to evasion of detection from
behaviour-and signature-based blocking as well as application
whitelisting.

Clean-application mimicry

AV systems are usually designed with a bias to avoid false
positives. This bias creates a loophole that can be exploited by
functional adaptation, because as the number of detections by
an AV system increases so do the false positives of each product.
As a consequence, the AV industry attempts to reduce the
footprint of signatures, but this can significantly amplify the
risks of exploitation by programs that have learned to mimic
clean applications either by behaviour or by signature.

Imagine that a program imports API function ‘Foo’, which
makes it similar to programs that create false positives for the
AV system. As a result, the presence of function Foo excludes
that program from the attention of behavioural blocking. This
problem exists even if the system uses weighting, as long as the
negative weights to identify possible clean applications can be
simulated by the newly evolved functions in malware M. There
are analogies for this type of evolutionary adaptation in biology.
Some viruses have evolved a set of proteins that mimic
precisely those proteins that are involved in combating the virus
(the so-called complement regulator proteins [20]), or else by
mimicking a protein that the immune system uses to recognize
viruses (so-called Fc proteins [21]). In both cases, the immune
system is fooled into treating the virus as ‘clean’ because it
looks like part of the immune system itself.

If malware M appears to have an application user interface, it
will most likely be classified as a clean application because
typical malware does not have one. In another example, if
malware M is not packaged or wrapped, it might appear much
less suspicious. Malware writers use packers extensively to hide
signatures from AV scanners. One of the cheapest ways for
attackers to do this is to use run-time packers or wrappers on
top of the existing malware. As a result, malware released in
packed form might look much more suspect than a non-packed
version. Evolving malware capable of presenting itself in both
packed and unpacked forms would create new challenges for
heuristics. There is a parallel to this evasion technique in
biological viruses. In fact, often a body’s immune system

triggers on the envelope (or capsid) of a virus. As a
consequence, some viruses have adapted to an infection mode
without an envelope and capsid (for example, the viroids [22]).
The reverse strategy also exists, where viruses such as the
herpes viruses, in an attempt to masquerade themselves as host
cells, create elaborate envelopes from host cell membranes that
contain a series of host-unique markers on them. Such
envelopes allow the herpes virus to evade host detection and
suppress immune responses [22].

Whitelisting deception

The practice of application whitelisting offers another exploit
for evolvable malware. Because the number of known
applications is already very high, typically application
whitelisting focuses only on executable applications (such as
Portable Executable files on Windows systems). As a
consequence, attacks originating from other types of objects
(such as documents) are not controllable by these systems.
Malware that is not presented in an executable form would thus
be excluded from the attention of whitelisting systems
completely. Self-evolving executable malware that could
convert itself to new forms, for example via executable-to-
script-conversion, would pose a challenge to any whitelisting
system. Instead of presenting itself as an executable, the code
might rewrite itself as a macro in a document, or as a
command-line script.

Another problem appears if there are no file objects involved, as
in the case of the W32/CodeRed family that targets a whitelisted
application in memory over the network. Not surprisingly, when
such threats emerge for the first time, they often cause an
epidemic. While in-memory threats are not common, their
presence is expected to rise if there is a need to adapt to a
known whitelisting solution.

Another scenario involving whitelisting deception could be the
following. Suppose a program creates large populations of clean
programs that it distributes over the web. However, the clean
programs are designed in such a way that their MD5 hash is
identical to its own (malicious) self [23]. Because whitelisting
applications collect executables from a variety of ‘trusted’
sources, the wide distribution of clean ‘twin’ programs could
have the result of whitelisting the malicious version. Thus, such
an attack can exploit both application whitelisting as well as
application reputation systems, which score applications based
on their popularity among users with good reputations. A simple
biological example of such an attack is represented by the
evasion of the DNA methylation defence of bacteria. Bacteria
tag their own DNA with a methyl group, and cut up any DNA
inside the cell that does not carry such a group (the methylation
is the analogue of an MD5 hash). Viruses have emerged that
have learned to emulate these tags (whitelisting themselves in
the process) and thus escape detection.

Virtual machine anti-emulation

It is conceivable that the size of a long function loop, or a
function that calculates parameters to function calls on the fly,
could be artificially increased by malware. In such a case, the
resulting novel functions might accidentally create an
anti-emulation feature for a virtual machine by exhausting the
emulator’s preset upper limit iteration number to examine the
program. This way, \( M \) will be capable of competing with an
emulator, thus exploiting this feature for its own survival. In this
case, the threat will be capable of circumventing not only
behavioural blockers that rely on emulators, but also a scanner’s
built-in heuristics analysers as well. Random sequences of APIs
with parameter-check can also introduce such issues. This trick
is often used by existing polymorphic threats as an
anti-emulation feature. The W95/Drill family of viruses utilized
random calls to a predefined set of APIs to confuse emulators.
Later on, the Storm worm attacks (that created the Storm
botnet) delivered thousands of copies of different malware
executables that utilized layers such as W32/Tibs on them to
confuse anti-virus products. The API sets used were changed by
the attackers regularly to reduce the chance of detection based
on the presence of such an API profile. A self-evolving threat
would carry this feature by its own nature, as it can create new
code and verification functions for them. We are not aware of a
biological analogy for this trick.

**Evasion by proxy**

Even security products such as personal firewalls can be
affected by self-evolving threats. Suppose threat \( M \) has a feature
to proxy behaviour using another executable. While the threat
may have several malicious features, it has the option either to
eexecute them itself, or by using a running application as a proxy
instead. As a result, when executing the communication via a
trusted application, the threat can remain undetected when
communicating to an outside location (such as the command
control channel of a bot network). Alternatively, all malicious
features might be separated among several processes as threads.
Imagine that a set of threads from a set of processes together
constitutes a malicious program. Yet, on its own, each feature
might not be triggering the attention of heuristics or the
behaviour-blocking engine, allowing the threat to escape
attention.

Trust relationships can also introduce problems. For example,
*Windows Vista* does not allow an executable to alter certain file
permissions, even if an administrator executes the application.
Still, using a script such permissions can be changed. For
example, files such as kernel32.dll and their permissions can
only be changed by so called Trusted Installers who have full
control over these files (see Appendix A). If one tries to change
the permission using CACLS.EXE from the Resource Kit, the
attempt will fail because this executable cannot be used to take
ownership of files, since it is not trusted. Yet, one can use
XCACLS.VBS, and execute it with CSCRIPT.EXE. The script
is trusted, since the script interpreter is a trusted application.
This means that threats can potentially evolve by changing their
representative forms (such as the particular language
environment they use) to develop adaptive features to a security
environment. What an executable is not able to due to
security restrictions might be achievable as soon as the threat
feature is executed as a script. In addition, using a trusted proxy
such as EXPLORER.EXE on *Vista*, a threat can take ownership
of files that otherwise it would not be allowed to do (for
example by using code injection techniques to become part of
the process address space of Explorer in memory).

---

**Environment-induced functional variation**

New functionality can emerge as a result of environmental
effects. Many websites, for example, change the code within
HTML files on the client side arbitrarily by presenting extra
functionality to the user. In particular, links to advertisement
messages can be replaced with actual content. In other cases,
scripts are inserted into pages, and changed on an ongoing basis
(see Appendix B). Such effects could change actual malware
code, rendering AV scanners incapable of identifying the threat.

We have seen several verified cases in the past where random
corruptions to virus code resulted in a new variant of the virus
that renders it undetected by security software. For example, a
variation of the W95/CIH family exists that is the result of such
a corruption: the replica escaped the attention of most scanners
when the natural modification happened to a piece of its
non-essential code, without altering the threat’s replication
functionality. In another case, an error in *Microsoft Word*
resulted in the creation of thousands of macro virus variants via
random corruptions. These macro-body corruptions were often
ignored by the macro interpreter due to the existence of error
handlers in the original virus code. As a consequence, these
*Word*-induced variations could easily result in surviving
mutations, as long as a single MacroCopy() command
responsible for the successful replication of the threat was still
present unchanged.

**Malware code merging**

A threat might be able to snatch code from another program in
its environment. We have seen examples of a virus like *Pinfi*
jumping on top of worms to replicate in new environments as a
combination threat. Security products do not always recognize
the worm once it is infected with a virus, and the combination
helps the survival of both threats. Disinfected worm copies can
also escape attention, as can copies of worm replicas that
changed due to the transfer of code over network channels. It is
conceivable that an evolutionary function in the malware could
snatch clean or malicious code from other programs. It could
integrate code from other programs by identifying function
prologue and epilogue code. When this takes place, a function is
safely inserted into the code base of the evolutionary virus as a
new “function” by running the newly acquired code as a new
thread. Existing features might be replaced by the code, which
could end up producing reliable output to a given input. (For
example, as long as function X returns values greater than 0, it
is accepted.) Even complete functionality might be snatched
from another clean program, or another virus. As previously
predicted [17], a cooperation protocol can enhance sharing of
features between malicious executables as well. Code snatching
is a tried and true function of almost all biological organisms.
Bacteria exchange code in small segments called plasmids,
while viruses routinely integrate bacterial code into their own.
Often, viruses carry this piece of code to other bacteria, a
phenomenon known as transduction.

A form of evolution was observed in macro viruses, which often
merge their code base into a document. (Note that the
integration of viral code into the host code is the default action
for several biological viruses, e.g. HIV [24].) Often the file has a
changes – even if collected under a single malware arises from these examples is whether small malware code unintended functional gains by malware. The question that induced adaptations to security environments, leading to the creation of chimeric viral particles. Taking these lessons back to computer malware, we predict that while this merging of code is still manageable for the anti-virus programs, cases when a clean macro is merged with a parasitic macro virus might not be. Imagine a random change that results in the macro code becoming very large, either as the result of several layers of merged code or additional polymorphisms. This can easily exhaust typical scanning engines for macro viruses due to memory limitations reserved for the macro code within the engines. As a consequence, an evolved copy can potentially escape just by being too large.

Code snatching can also lead to detection evasion if the snatched code is clean, and triggers the heuristic based on code snippet-based exclusions, leading to effects similar to those mentioned under the heading ‘Clean application mimicry’. Once a copy of the malware snatches the code snippet ‘exclude’ from a clean program and presents it within itself at the right place, the scanner might ignore the malware. While the scanner would trigger on the rest of the code, the exclusion forces it to fail. Such exclusion strings were extracted from several AV systems in the past, and shared among attackers to be included in viruses [25]. As this example shows, it is not necessary for a human to disassemble the anti-virus programs to gain this knowledge: random code snatching can easily produce it. And once it is produced it will flourish, as it will escape detection.

**HOW FAR CAN EVOLUTION GO?**

We have reviewed numerous examples of non-evolution-induced adaptations to security environments, leading to unintended functional gains by malware. The question that arises from these examples is whether small malware code changes – even if collected under a single malware implementation – are sufficient for the evolution of the functional complexity exhibited by biological viruses. Let us first consider how much functionality and complexity can possibly be generated by the process of random changes and subsequent selection. Biologists often use the vertebrate eye as an example of how complexity can arise through evolution. It is rather difficult to imagine such an organ with its hundreds of millions of photocells and hundreds of different chemicals required to process a single image being created from scratch. Instead, it is easier to imagine a historical succession of eyes that differ only slightly from each other, and where one originates from the other via only small and gradual changes or mutations. In a collection of all possible mutations a version of the eye can undergo, large ones are statistically more improbable than smaller ones. Hence, a long string of such small mutations occurring gradually through geological time could connect ancestral versions of the eye to more recent highly functional ones that have the look and feel of design. If we were to follow all these changes through time, it would become apparent instead that ancestral versions are only slightly different from their direct descendants. Indeed, we can see just such a succession of changes when looking at the vast variety of eyes and eye-like structures present in surviving species. From pigment enriched, light-sensitive spots in some single-celled animals to elementary eye-like pigmented cavities in several shellfish, the evolution of eye structures can be mapped out [26]. By analogy, we can imagine the emergence of arbitrary complexity in autonomously evolving computer viruses. The myriad examples mentioned above of unintended virus behaviours due to random changes are all examples of more complex behaviours originating from simpler ones through small programming jumps. As in biology, the collection of software and APIs in an operating system environment is sufficient for providing a pool of features that a virus can choose to sample. Those features that provide the virus with an evolutionary advantage (e.g. escaping detection, infecting different platforms, etc.) will be propagated, leading to unanticipated complex behaviours. The only question that remains is whether such a sequence of events is likely within time frames much shorter than the geological time available to the biological process. Lenski et al. have shown that complex functionality can evolve from much simpler functions in Artificial Life platforms over the course of a few days [13], and complex adaptations have been seen to emerge after tens to tens of thousands of generations [15,16], easily within a range of weeks of malware evolution.

Research in Artificial Life of the sort mentioned earlier has identified a number of important parameters that need to be satisfied before complexity can evolve. First and foremost are of course the three conditions for Darwinian evolution themselves: replication, variation and selection. Of those, replication and selection are naturally present, and we argued above that variation can occur via a variety of mechanisms. However, in order for sufficient variation to be present so that selection can act efficiently, population sizes should be large. Finally, the number of variants (mutants) with non-zero fitness (sometimes called the neutral fraction of mutants) should be sizeable. It has been shown that ideally between 10% and 40% of all mutations experienced by a population need to be neutral to ensure evolvability [7]. (Note that the fraction of mutants of biological proteins is also in that range [27].) Neutrality enables the organism to better sample the pool of available mutations by being able to discover beneficial mutants without constantly being penalized by the already high frequency of deleterious mutations. Beneficial mutations are hard to come by in a single try, but can become more likely if interspersed by a series of neutral ones. In essence, neutral mutations allow organisms to buy more time in their quest for discovering survivability-enhancing traits. Applying this lesson back to computer language implementations, it is easy to see why mutating binary code would make it impossible to discover new functionality: the fraction of neutral changes is just too low. On the contrary, integration of pieces of functional code and/or importing functions and APIs available in the computer
environment have a much higher probability of being neutral, and on a rare occasion even beneficial.

Through several experiments it was shown that Alife organisms could indeed evolve complexity as long as the intermediate steps that lead to it could be sampled, i.e. the simple functions that are required to build more complex ones can be attained via mutations [13]. It is also interesting to note that this complexity was attained by different populations in a variety of environments, hinting at what biologists refer to as convergent evolution. If a trait produces a significant survival advantage to an organism (be it eye, wings, lungs etc.), it will be evolved by unrelated organisms that occupy different environments, in one form or another. What does this mean for computer malware? If computer malware is implemented using the principles of Darwinian evolution and an implementation construct allowing sufficient neutrality, the emergence of complex adaptive behaviours becomes an expected result rather than an improbability, as long as exploitable opportunities exist within the malware’s environment. We have listed a number of those here, and are certain that many more can be imagined.

CONCLUSION

It has already been discussed by other researchers that no virus detection algorithm can detect all possible viruses, known and unknown [28, 29]. The same researchers have also mentioned the possibility of a Darwinian evolution-based malware implementation. So far, no one has attempted to investigate how feasible such an implementation is or assessed the implications it could have, given the current methods of detection. We have shown here through a series of historical malware examples as well as a theoretical implementation model that a truly undetectable virus might be more feasible than previously imagined. By using an evolutionary function, computer malware could implement traits and tricks that allow them to mimic clean application behaviour, have themselves whitelisted, avoid signature-based detection, or recruit proxies to do their bidding. More importantly, malicious programs could conceivably alter their functionality so as to discover new exploits or find new platforms to infect, with the same ease that biological viruses gain immunity to anti-viral drugs, or adapt to new hosts.

The development of sophisticated encryption techniques and metamorphic viruses has led to weakened performance of AV systems based on databases of signatures alone. Behaviour-based detection, (relying instead on libraries of behaviours obtained from emulation or from runtime code on the system) has been developed as a stop-gap measure. If malware is developed that can evolve via Darwinian principles, behaviour-based blocking is weakened too, as the discovery of even trivial new functionality would have the potential to evade detection. Would there be no defence against such viruses? The answer to this question is currently unclear. The general problem of computer virus detection is inherently an integrity problem, and thus managing integrity is essential for the protection of the system. Yet, as the examples for evolution of malware threats have demonstrated, over time the definition of integrity may need to be continuously updated. On the one hand, it is clear that the emergence of an evolvable threat could be potentially disastrous. On the other hand, it is entirely possible that evolution will in most cases lead to harmless forms of a threat, as is often observed in biology. Finally, even though both the signature and the behaviour of an evolvable threat may be highly variable, it is still possible that such threats rely on common algorithmic features for which detection methods can be developed. What these commonalities are is, of course, presently unknown.

ACKNOWLEDGEMENTS

We would like to thank N. Chaumont, P. Ferrie, V. Griffith, A. Hintze, A. Nash, C. Ofria, and M. Rupp, for discussions and comments on the manuscript. This research was supported in part by the Seaver Foundation.
